Abstract

The popularization of cloud computing has brought a concern over the energy consumption in data centers. In addition to the energy consumed by servers, the energy consumed by the large number of network devices emerges as a significant problem. Existing work on energy-efficient data center networking primarily focuses on traffic engineering, which is usually adapted from traditional networks. We propose a new framework to embrace the new opportunities brought by combining some special features of data centers with traffic engineering. Based on this framework, we characterize the problem of achieving energy efficiency with a time-aware model, prove its NP-hardness and solve it in two steps. First, we solve the problem of assigning virtual machines (VM) to servers to reduce the amount of traffic and to generate favorable conditions for energy-efficient routing. The solution proposed for this problem is based on three essential principles we propose. Second, we reduce the number of active switches and balance traffic flows, depending on the relation between power consumption and routing, to achieve energy conservation. Experimental results show that, by using the whole framework, we can achieve up to 50% energy savings. Extensions to general cases prove that our method is scalable and practical in use.

Keywords: Data Center Networks, Energy Efficiency, Virtual Machine Assignment, Traffic Engineering

1 Introduction

Data centers are integrated facilities to house computer systems for cloud computing, and have been widely deployed in big companies, such as Google, Yahoo!

and Amazon. The energy consumption of data centers has become an essential problem. It is shown in [?] that the electricity used in global data centers in 2010 likely accounted for between 1.1% and 1.5% of total electricity use and it is still increasing. However, while energy saving techniques for servers have evolved, the energy consumption of the enormous amount of network devices used to interconnect servers has emerged as a substantial issue. Abts et al. [?] showed that in a typical data center from Google, the network power is around a fraction of 20% to the total power with 100% utilized servers, but it increases to 50% when the utilization of servers decreases to 15%, which is quite realistic in production data centers. Therefore, improving the energy efficiency of the network also becomes a primary concern.

There is a large body of work in the field of energy efficiency in Data Center Networks (DCNs). While some energy-efficient topologies have been proposed ([?], [?]), most of the works are focused on traffic engineering, trying to consolidate flows onto a subset of links and switch off unnecessary switches ([?], [?], [?], [?]). These solutions are generally based on characterizing the traffic pattern by prediction, which is usually not feasible or is not precise enough because the traffic patterns vary significantly depending on the different applications.

We believe that in order to improve the energy efficiency in DCNs, the unique features of data centers should be explored and utilized. In particular, we think that the following features should be taken into account:

- a) Regularity of the topology: compared to traditional networks, DCNs using new topologies, such as fat-tree [?], BCube [?] and DCell [?], are more regular and symmetric. As a result, it is possible for us to have better knowledge about the physical network.
- b) VM assignment: due to virtualization, we can determine the endpoints of traffic flows, which will have a remarkable influence on the traffic carried by the network and will, consequently, condition traffic engineering.
- c) Application characteristics: most applications in cloud data centers are run under the MapReduce paradigm [?], bringing about regular and recognizable communication patterns. Making use of these characteristics can help us get rid of the traffic prediction and obtain better traffic engineering results.

In order to fully seize these new opportunities, we propose a new general framework (as illustrated in Figure 1) for achieving energy efficiency in DCNs, where the particular information of both the applications and the network will be deeply explored and coherently utilized. We will carefully design the VM assignment based on a comprehensive understanding of the applications characteristics and combining them with the aforementioned network features (e.g. topology, end-to-end connectivity and communication bandwidth). This purposeful VM assignment will provide us favorable traffic conditions on the DCN and thus gain us some energy savings in advance before carrying out the traffic engineering on the network. Then, we will explore particular traffic engineering solutions according to the specific traffic patterns and network features.

Figure 1: A new general framework for achieving energy efficiency in DCNs

The main contributions of this paper are highlighted as follows. First, we provide a new general framework for the energy minimization in DCNs. We also carry out exhaustive analysis on how to proceed with this framework and enumerate new issues and challenges. Second, we model the energy-saving problem in DCNs by using this new framework and prove its hardness. Third, we provide in-depth analysis on both VM assignment and network routing with respect to energy conservation, showing that there is a big room for improving the energy efficiency by making use of some unique features of data centers. Fourth, based on the analytical results, we provide efficient algorithms to solve the problem. We also conduct comprehensive experiments to evaluate the efficiency of our method.

The rest of this paper is organized as follows. In Section 2, we describe the general framework and discuss how it can be erected. In addition, we list some newly arising issues. In Section 3, we present a time-aware model to describe the energy-saving problem in DCNs based on the new framework and analyze its hardness. We explore VM assignment principles for energy saving and provide a traffic-aware energy-efficient VM assignment algorithm in Section 4. The routing optimization is addressed in Section 5 where we present detailed theoretical analysis and provide a two-phase energy-efficient routing algorithm. Section 6 provides the experimental results and Section 7 presents some extended discussions on the practicality of our algorithms. In Section 8, we summarize related work and in Section 9, we draw a simple conclusion.

2 The General Framework

Although we are considering the problem of achieving energy efficiency in DCNs, this framework can also be generalized for most of the performance optimization problems in DCNs. In this section, we discuss in general how to conduct optimization work by using this framework and list some new challenges. The structure of this new framework has been illustrated in Figure 1.

Applications. As an important paradigm for large-scale data processing,

Figure 2: A fat-tree topology with 16 servers connected

MapReduce [?] has been widely applied in modern cloud data centers of many big companies. Most cloud applications have been ported to MapReduce. For this reason, we focus our attention on typical MapReduce jobs. A typical MapReduce job comprises three main phases: Map, Shuffle and Reduce. The network is only intensively used in the Shuffle phase in order to exchange intermediate results between processors. As a result, MapReduce-type applications usually own regular communication patterns. Xie et al. [?] profiled the network patterns of several typical MapReduce jobs, including Sort, Word Count, Hive Join, and Hive Aggregation, which represent an important class of applications residing in data centers. They observed that all these jobs generate substantial traffic during only 30%-60% of the entire execution, and the traffic patterns of these jobs can mainly be classified into three categories: single peak, repeated fixed-width peaks and varying height and width peaks. Having this in mind, the network traffic can be scheduled in advance, which will completely change the traffic engineering results.

The characteristics of applications can be obtained by profiling runs of jobs. The detailed profiling method is out of the scope of this paper, but one possible realization can be found in [?]. The profiling process may bring ineluctable profiling overhead, but it can be drastically reduced if the same types of jobs with the same input size are run repeatedly. We observe that such scenario is quite common in cloud data centers for iterative data processing such as PageRank [?] where much of the data stays unchanged from iteration to iteration, and also in many production environments (e.g. [?]), the same job needs to be repeated many times with almost identical data.

Data center networks. In order to provide reliability and sufficient bisection bandwidth, many researchers have proposed alternatives to the traditional 2N tree topology [?]. By providing richer connectivity, topologies such as fat-tree ([?, ?]), BCube [?], DCell [?] and VL2 [?] can handle failures more gracefully. Among them, fat-tree was proposed to use commodity Ethernet switches to support the full aggregate bandwidth in large-scale data centers. As shown in Figure 2, a fat-tree is built from a large number of richly connected switches, and can support any communication pattern with full bisection bandwidth.

Apart from that, the DCN can bring us another special benefit, the regularity of the topology. Most topologies being used in DCNs follow a multi-tier tree

architecture. The scalability of such topologies is always achieved by scaling up each individual switch, i.e. by increasing the fan-out of single switches, rather than scaling out the topology itself. Since such topologies in different scales always possess almost the same properties, the optimization efforts we make for small-scale networks can be easily adapted to large-scale ones with very slight changes. This enables us to make use of the unique features of the well-structured topologies to improve network performance by gaining insights from small-scale networks.

VM assignment. To improve flexibility and overall hardware-resource utilization, virtualization has become an indispensable technique in the design and operation of modern data centers. Acting as a bridge, VM assignment provides the possibility of combining the characteristics of applications and traffic engineering. With the goal of improving the performance of the network, VM assignment can be accomplished by integrating the characteristics of the running applications and the special features of the network topology. For instance, knowing the traffic patterns of applications, we can schedule jobs in a way that their communication-intensive periods are staggered or jobs with similar communication patterns are separated into different areas of data centers. As a consequence, the load on the network will be more balanced and the network utilization will be accordingly improved. By assigning VMs in an appropriate way, we will be able to obtain better initial conditions for the following traffic engineering.

Traffic engineering. As a conventional approach for the optimization of network performance, traffic engineering has also been extensively investigated in DCNs. Most of the traffic engineering solutions being used in current data centers are simply adapted from traditional networks. In a traditional operational network, traffic engineering is usually carried out by traffic measurement, characterization, modeling and control. However, with the specific features that characterize DCNs, traffic engineering could be quite different from those conventional ones. Using the information of traffic patterns provided by VM assignment, a better understanding on traffic can be achieved and, consequently, traffic measurement and characterization can be eliminated, leading to more precise traffic engineering results. At the same time, we can also take advantage of the unique features of the DCN topology and design elaborate traffic engineering solutions in particular.

Under this new framework, there are some newly arising issues and challenges that may need future research efforts.

- a) The applications running in current data centers show regular communication patterns and can be obtained by profiling. However, the profiling method will directly condition the accuracy of this information. As a result, effective and efficient profiling methods are eagerly desired.
- b) Different metrics for network performance may prefer different favorable traffic conditions, which are conditioned by VM assignment. Thus, understanding the favorable traffic conditions and designing efficient VM assignment algorithms to generate them are crucial in this framework.

- c) The universal traffic engineering solutions may not be efficient enough for current DCNs. In order to obtain better results, specific traffic engineering methods for each particular data center need to be explored by making use of both the topology features and the traffic patterns known in advance.

3 Modeling the Energy-Saving Problem

In this section, we focus on the energy saving problem. By using the proposed framework, we present a temporal model for it and prove its hardness. We start with some preliminary modeling.

3.1 Data Center and Data Center Network

We consider a data center as a centralized system where a set of servers are connected by a well-designed network. Suppose there are m servers represented by set M . To achieve better utilization of hardware resources, jobs are processed by VMs which are hosted by servers. All the servers are connected by a network $G = (V, E)$, where V is the set of switches and E is the set of links. In this work, we focus on switch-centric physical network topologies and use the most representative one, fat-tree, to conduct our work. For each node $v \in V$, the total traffic load it carries can be expressed by $x_v = \frac{1}{2} \sum_{\{e|v \text{ is incident to } e\}} y_e$, where y_e is the total traffic carried by link e . The factor $1/2$ avoids counting each flow twice.

For a single network device, energy-saving strategies have been widely explored. Among them, *speed scaling* ([?, ?, ?, ?]) and *power down* ([?, ?]) are two representative techniques. The former aims to adaptively reduce the transmission rate of a network device when the traffic going through it decreases, resulting in energy savings. This is based on the observation that during most of the time, the network carries little traffic compared to the peak. Although it might be more complex to manufacture network equipments having this functionality, there have already been some kinds of network devices designed with variable operating rates, such as InfiniBand [?] and Cray YARC [?]. The latter is to switch off a network device when it is idle, bringing substantial reduction on energy consumption. In this paper, we use both strategies in an integrated way. More precisely, we characterize the power consumption of a switch $v \in V$ by an energy curve $f_v(x_v)$, which indicates how v consumes power as a function of its transmission speed x_v . Usually function $f_v(x_v)$ can be formalized as

$$f_v(x_v) = \begin{cases} 0 & \text{for } x_v = 0 \\ \sigma_v + \mu_v x_v^\alpha & \text{for } x_v > 0 \end{cases}, \quad (1)$$

where σ_v represents a fixed amount of power needed to keep a device active, and μ_v and α are parameters associated with devices. This way, if a network device carries no load, it can be shut down and incurs no cost. Otherwise, an initial cost is paid at the beginning and then, the cost goes up as the assigned load

increases. We assume that the power consumption of a network device grows superadditively with its load, being α usually larger than 1 (it has been shown in (1,3) [?]). Due to the homogeneity in DCNs, it is convenient to assume a uniform cost function $f(\cdot)$ for all switches. The total cost of a network is defined as the total power consumption of all of its network devices, given by $\sum_{v \in V} f(x_v)$.

3.2 Applications

Now we characterize the communication patterns of the applications. As we discussed before, the applications can be classified into three main categories according to their communication patterns. For the simplicity of exposition, here we use the single peak pattern as an example. Later, we will discuss how to adapt our results to other patterns.

Assume we are given a set of k jobs, represented by J , that have to be processed simultaneously during our interested period of time $[t_1, t_r]$. The time unit is chosen according to the traffic patterns of jobs such that during each unit of time, the traffic is relatively stable. Each job $j \in J$ comprises n_j tasks each of which has to be processed on a pre-specified VM. For each job $j \in J$, we assume a time period $[t_{js}, t_{jt}] \subseteq [t_1, t_r]$ during which the traffic of this job is substantial and, for each unit of time $t \in [t_{js}, t_{jt}]$, a traffic matrix $\mathbf{T}_j(t)$ of size $n_j \times n_j$ is given to indicate the communication pattern of job j at that time. For $t \in [t_1, t_{sj}) \cup (t_{tj}, t_r]$, we assume there is only very small background traffic and has small influence to the network.

3.3 Problem Description

We describe now the energy-saving problem in DCNs and provide a time-aware network energy optimization model to redefine this problem. We assume that the VMs of jobs will not be migrated once they have been assigned. Because in cloud data centers, jobs are usually very small and need to be repeated for many times [?]. For example, the average completion time of a MapReduce job at Google was 395 seconds during September 2007 [?]. Nevertheless, we leave the case where VM migration is involved as future work. With the modeling of DCNs and jobs, the total energy consumed by all the network elements for processing all the jobs then can be represented by $EN = \sum_{t=t_1}^{t_r} (\sum_v f(x_v(t)))$, where $x_v(t)$ is the load of node v at time t . Our goal is to assign all the VMs to servers such that when we choose appropriate routing paths for the flows in between each pair of VMs in communication, the total cost EN is minimized.

The optimization procedure can be divided into two closely related stages: VM assignment and traffic engineering. Given an assignment of VMs, the total cost can be minimized by applying traffic engineering on the network, which solves an energy-efficient routing problem. We first assume that an algorithm $\mathcal{A}$ has been given to solve this routing problem. Then, the VM assignment

problem can be modeled by the following integer program.

$$\begin{aligned}
& (P_1) \quad \min \quad \sum_{t=t_1}^{t_r} \mathcal{A}(D(t)) \\
& \text{subject to} \quad \sum_x z_{ix} \cdot c_x \leq C_r & \forall i \\
& \quad \sum_{1 \leq i \leq m} z_{ix} = 1 & \forall x \\
& \quad z_{ix} \in \{0, 1\} & \forall i, x
\end{aligned}$$

where z_{ix} indicates whether the VM x is assigned to the i -th server ($1 \leq i \leq m$). c_x is the abstract resource required by VM x and C_r is the total amount of resource in one server. The second constraint means that each VM can and only can be assigned to one server. $D(t)$ is a set of traffic demands to be routed at time t . Each demand in $D(t)$ is indicated by a triple consisting of a source, a destination and a flow amount. Once an assignment is given, $D(t)$ can be obtained by the traffic patterns of jobs at time t .

Now we dispose of the energy-efficient routing problem that algorithm $\mathcal{A}$ aims to solve. After obtaining the traffic demands $D(t)$, this problem can be represented as follows: given a network $G = (V, E)$ with a node cost function $f(\cdot)$ and a set of traffic demands $D(t)$, the goal is to unsplittably route every demand in $D(t)$, such that the total cost of the network $\sum_v f(x_v)$ is minimized, where x_v is the total load on node v . Formally, it can be formulated as the following integer program.

$$\begin{aligned}
& (P_2) \quad \min \quad \sum_v f(x_v) \\
& \text{subject to} \quad x_v = \frac{1}{2} \sum_{v \in e} y_e \leq C & \forall v \in V \\
& \quad y_e = \sum_{i \in [1, |D(t)|]} y_{i,e} & \forall e \\
& \quad y_{i,e} \in \{0, 1\} & \forall i, e \\
& \quad y_{i,e} : \text{flow conservation}
\end{aligned}$$

where $y_{i,e}$ is an indicator variable to show whether demand i ($1 \leq i \leq |D(t)|$) goes through edge e . Flow conservation means only a source (sink) node can generate (absorb) flows, while for other nodes, the ingress traffic equals the egress traffic. y_e is the total load carried by link e , and x_v is the total traffic going through node v and will never exceed the capacity C .

3.4 Hardness Analysis

We now analyze the computational complexity of this problem. Actually, the NP hardness can be proved by a reduction from the general Quadratic Assignment Problem (QAP), which describes the following problem: there is a set of n facilities and a set of n locations. A distance and a weight are specified for each pair of locations and facilities respectively. The problem is to assign all facilities to different locations with the goal of minimizing the sum of the distances multiplied by the corresponding weights. QAP was first studied by Koopmans and Beckmann [?] and is well known to be strongly NP-hard. Moreover, achieving any constant approximation for the general QAP is also NP-hard. It is believed

that even obtaining the optimal solution for a moderate scale QAP is impossible [?]. Formally we show

Theorem 1. *Finding the optimality of the energy-saving problem in DCNs is NP-hard.*

Proof. We prove it by showing that any polynomial-time deterministic algorithm that can obtain the optimal solution for our energy-saving problem can be used to solve QAP. Suppose we are given an instance of QAP with n locations and n facilities. For these locations and facilities, we are also given two matrices $\mathbf{M}_d$ and $\mathbf{M}_c$ of size $n \times n$ to indicate the distance between each pair of locations and the cost between any two facilities respectively. The total cost of this QAP instance is

$$\sum_{i_1, i_2 \in [n]} \mathbf{M}_d(i_1, i_2) \mathbf{M}_c(\pi(i_1), \pi(i_2)) \quad (2)$$

where π is a permutation of $[n]$. The reduction from QAP to our problem is built as follows: 1) create n nodes for servers; 2) for each pair of servers, connect them by a single switch; 3) for a switch connecting two servers s_{i_1} and s_{i_2} , define its energy consumption function as $g_{i_1 i_2}(x) = \sigma + \mathbf{M}_d(i_1, i_2)x^\alpha$, where σ is a constant and $\mathbf{M}_d(i_1, i_2)$ is the distance between the i_1 -th and the i_2 -th locations in the QAP instance. We treat the facilities as a set of VMs and the α root of the cost between any two facilities ($\mathbf{M}_c$)^{1/ α} as the traffic flow between the corresponding VMs. This way, the corresponding energy-saving problem is to allocate each VM into one server such that the total energy consumption is minimized. Given an assignment of VMs π (a permutation of $[n]$), the total energy consumption can be expressed by

$$\sum_{i_1, i_2 \in [n]} \left(\sigma + \mathbf{M}_d(i_1, i_2) \left(\mathbf{M}_c(\pi(i_1), \pi(i_2))^{1/\alpha} \right)^\alpha \right). \quad (3)$$

It can be found that the only difference between the total cost of the QAP instance (as in (2)) and the one in our problem (as in (3)) is a constant value $n^2\sigma$. Therefore, when we obtain the optimal solution for our problem, the corresponding assignment is also optimal for the corresponding QAP. As a result, any polynomial time deterministic algorithm optimally solving the energy-saving problem in DCNs can be borrowed to solve QAP. That ends the proof. $\square$

4 Exploring Energy-Efficient VM Assignment

In this section, we seek energy-efficient VM assignment strategies by exploiting some unique features of the usually well-structured topologies of DCNs. Combining this with the analysis of the characteristics of the applications, we provide three main principles to guide the VM assignment. Based on these principles, we propose a traffic-aware energy-efficient VM assignment algorithm. First of all, we provide the following prerequisites.

Table 1: Power Rating Profiles of Some Typical Commodity Switches (Unit: Watts)

Product	Idle or Nominal	Max
Cisco Nexus 3548	152	265
Cisco Nexus 5548P	390	600
HP 5900AF-48XG	200	260
HP 5920AF-24XG	343	366
Juniper QFX 3600	255	345

Definition 2. The **power rate** of a network device is defined as the power consumed by every unit of load it carries, i.e., $f(x)/x$ ($x > 0$).

Proposition 3. Ideally, the total power consumption of a network is minimized when all the network devices carry the load $R^* = \left(\frac{\sigma}{\mu(\alpha-1)}\right)^{1/\alpha}$, given a certain amount of traffic.

Proof. Recall that the cost function of each network device is defined in a constant and a load dependent part (indicated in (1)) and, the optimal solution aims to balance them because of the convexity of the load dependent cost. Another observation is that given a certain amount of traffic, the sum of the total amount of traffic carried by all the switches in the network is invariable, no matter how the traffic is routed, because the paths connecting each pair of servers have equal lengths. Based on these, it is natural to see that the total power consumption of a network is minimized when the power rate of every network device is minimized. That is, we minimize $(\frac{\sigma}{x_v} + \mu x_v^{\alpha-1})$, for each $v \in V_a$ where $V_a \subseteq V$ is the set of active switches. This can be achieved by choosing all x_v to be $\left(\frac{\sigma}{\mu(\alpha-1)}\right)^{1/\alpha}$, denoted as R^* . $\square$

However, this proposition may not be able to directly apply in reality. According to the statistics in [?], the idle power consumption of a 48-port edge LAN switch ranges from 76 Watts to 150 Watts, while working at full speed, about 40 Watts or more can be added. Also in [?], the authors measured the power consumption on a production PRONTO 3240 OpenFlow-enabled switch and obtained a very similar result. In order to confirm this finding, we collected the power rating profiles of some commodity switches from the vendors' websites. The detailed information can be found in Table 1. This proves that the idle power usually takes a big portion of the total power consumption. This basically means that the startup cost σ in our model is quite high. As a consequence, it is more likely to have $R^* > C$. However, as the load in a switch cannot be larger than C , Proposition 3 might not be applied. In order to respect this finding, we will assume in the rest of this work that $R^* > C$ which in turn is $\sigma \geq \mu(\alpha-1)C^\alpha$.

Figure 3: Two ToR switches connected by a network with a general topology

4.1 VM Assignment Principles

We now propose the principles for VM assignment that need to be followed for achieving better energy efficiency in DCNs. We use a *bottom-up* analyzing approach, i.e., in a fat-tree, we focus on racks, pods and then the whole data center at last.

4.1.1 Arranging VMs into Racks

We first concentrate on Top-of-Rack (ToR) switches, as ToR switches are different from other ones in the network. Once there is at least one server active in that rack, the corresponding ToR switch cannot be shut down because there might be some inter-rack traffic. Also ToR switches have to carry the intra-rack traffic which cannot be derived to other switches. As a result, the power consumption of ToR switches will be largely conditioned by VM assignment. The following result can help us determine the right number of ToR switches.

Theorem 4. (*Principle 1*) *The optimal VM assignment consists in compacting VMs into racks as tightly as possible in order to minimize the power consumption of ToR switches.*

Proof. We focus on two arbitrary ToR switches in a fat-tree like the one in Figure 3. Let A and B represent the set of VMs assigned to the servers connected with the two switches respectively. In order to conduct our comparison, we assume, without loss of generality, that all the VMs in set B can be accommodated into the left-side servers without violating the resource capacity. Assume the traffic between each pair of VMs in A and B is characterized by a matrix $\mathbf{Q}$, where $\mathbf{Q}(x, y)$ indicates the traffic flow sent from VM x to VM y . Denote $X = \sum_{x \in A} \sum_{y \in A} \mathbf{Q}(x, y)$, $Y = \sum_{x \in A} \sum_{y \in B} \mathbf{Q}(x, y)$, $Z = \sum_{x \in B} \sum_{y \in A} \mathbf{Q}(x, y)$, and $W = \sum_{x \in B} \sum_{y \in B} \mathbf{Q}(x, y)$.

For the setting we have in Figure 3, apart from the energy consumed by the switches lying in the intermediate network, the total network power consumption incurred by the traffic generated by VMs in A and B is represented by $P_1 = 2\sigma + \mu(X + Y + Z)^\alpha + \mu(Y + Z + W)^\alpha$. Then, we consider an alternative assignment where we move all the VMs in B to the left-side servers. On one hand, the right-side ToR switch can then be shut down in order to save energy, as there will be no VM in the right side. Moreover, the power consumption on the intermediate network will be reduced because of traffic decrease. On the

other hand, the traffic load carried by the left-side ToR switch will increase, resulting in more power consumption. The total power consumed by the two ToR switches after this VM consolidation becomes $P_2 = \sigma + \mu(X + Y + Z + W)^\alpha$. We now compare the power consumption in the above two cases. We denote ΔP as the difference between them. Then, we have

$$\Delta P \geq \sigma + \mu((X + Y + Z)^\alpha + (Y + Z + W)^\alpha - (X + Y + Z + W)^\alpha).$$

Now we consider the following two cases.

Case 1: $\alpha \geq 2$. As $\sigma \geq \mu(\alpha - 1)C^\alpha$, we have $\sigma \geq \mu(\alpha - 1)C^\alpha \geq \mu C^\alpha \geq \mu(X + Y + Z + W)^\alpha$. The third inequality follows from $X + Y + Z + W \leq C$. Then, we have $\Delta \geq 0$.

Case 2: $1 < \alpha < 2$. We define function

$$f(Y, Z) = (X + Y + Z)^\alpha + (Y + Z + W)^\alpha - (X + Y + Z + W)^\alpha.$$

It is easy to check that the partial derivatives of $f(Y, Z)$ where both Y and Z are non-negative, i.e., $\frac{\partial f(Y, Z)}{\partial Y} \geq 0$ and $\frac{\partial f(Y, Z)}{\partial Z} \geq 0$. This means that function $f(Y, Z)$ is monotone increasing with both Y and Z . By setting $Y = Z = 0$ we have

$$\begin{aligned} \Delta P &\geq \sigma + \mu(X^\alpha + W^\alpha - (X + W)^\alpha) \geq \mu C^\alpha(\alpha - 1) + \mu(2(\frac{C}{2})^\alpha - C^\alpha) \\ &= \mu C^\alpha(\alpha + \frac{1}{2^{\alpha-1}} - 2) \geq 0 \end{aligned}$$

The second inequality comes from the fact that $X^\alpha + W^\alpha - (X + W)^\alpha$ is minimized when $X = W = C/2$ with $X + W \leq C$. The last inequality can be easily verified.

In one word, $\Delta P \geq 0$ holds for any $\alpha > 1$, so consolidating VMs will provide us a better energy efficiency for the two ToR switches. As a result, reducing the number of ToR switches as possible will always improve the network energy efficiency. As we have stated, this supposes compacting VMs into racks as tightly as we can, which completes the proof. $\square$

4.1.2 Arranging VMs in one Pod

We now discuss how to allocate VMs in one single pod. It is obvious that we will have no chance to switch off any ToR switches if the above principle has been applied. Based on this, we assume a scenario where there are a few jobs whose VMs are assigned into one pod but no job except one has dramatic traffic among its VMs at a certain time. Now we discuss how to arrange the VMs of that job into racks in this pod in order to reduce the power consumption of the switches. Basically, the following result can be obtained.

Theorem 5. (Principle 2) Suppose there are K racks in one pod, where $K \geq 4^{\frac{\alpha}{\alpha-1}}$. Then, distributing the VMs into k racks will incur less power consumption compared to compacting the VMs into one single rack, where $4^{\frac{\alpha}{\alpha-1}} \leq k \leq K$.

Proof. Suppose we are given a set of jobs in which there is only one job that has significant networking requirements. We focus on the assignment of the VMs for this job. First, we consider an even distribution of these VMs in k different racks. We denote the intra-rack traffic on each ToR switch as u_i ($1 \leq i \leq k$) and the inter-rack traffic between the i_1 -th and the i_2 -th rack as $w_{i_1 i_2}$ ($1 \leq i_1, i_2 \leq k$). Assume we only use half of the aggregation switches to carry the load evenly, which is quite conservative with respect to the energy-saving strategies for routing (because we will need to shut down some switches later). The total power consumption of the switches incurred by traffic loads in this pod is

$$P_1 = \sum_{i_1=1}^k \left(u_{i_1} + \sum_{i_2 \neq i_1}^k w_{i_1 i_2} \right)^\alpha + \frac{k}{2} \times \left(\frac{\sum_{i_1=1}^k \sum_{i_2 \neq i_1}^k w_{i_1 i_2}}{2 \times \frac{k}{2}} \right)^\alpha,$$

while assigning all the VMs into one single rack supposes a total power consumption of

$$P_2 = \left(\sum_{i=1}^k u_i + \frac{\sum_{i_1=1}^k \sum_{i_2 \neq i_1}^k w_{i_1 i_2}}{2} \right)^\alpha.$$

For the sake of tractability, but without loss of generality, we consider the case where all the u_i are roughly equal, denoted as u , and all the $w_{i_1 i_2}$ are also roughly identical, denoted as w . Define $\Delta P = P_2 - P_1$. Then, we have

$$\begin{aligned} \Delta P &= \left(ku + \frac{k(k-1)}{2}w \right)^\alpha - k(u + (k-1)w)^\alpha - \frac{k}{2}((k-1)w)^\alpha \\ &\geq k^\alpha \left(u + \frac{(k-1)w}{2} \right)^\alpha - k((u + (k-1)w)^\alpha + ((k-1)w)^\alpha) \\ &\geq k^\alpha \left(u + \frac{(k-1)w}{2} \right)^\alpha - k(u + 2(k-1)w)^\alpha \\ &> (k^\alpha - k4^\alpha) \left(u + \frac{(k-1)w}{2} \right)^\alpha > 0, \end{aligned} \tag{4}$$

where the second inequality is due to the convexity of the power consumption incurred by traffic loads, and the last inequality comes from our assumption that $k \geq 4^{\frac{\alpha}{\alpha-1}}$. Thus, as long as $K \geq 4^{\frac{\alpha}{\alpha-1}}$, it is possible to distribute all the VMs to all servers in one pod in order to reduce the power consumption. $\square$

The intuition behind this principle is that distributing VMs among multiple racks will move some traffic from the ToR switches to the upper-layer network. With the rich connectivity provisioned in the upper-layer network and the convexity property of energy consumption, this will bring a potential benefit in energy saving. For instance, if $\alpha = 2$, as long as we evenly distribute the VMs for one job to $k = 16$ or more racks, the energy consumption will be reduced compared to compacting them into one rack. In production data centers, having more than 16 racks in one pod is quite realistic. As we are considering big data

centers, we can claim that K is not smaller than $4^{\frac{\alpha}{\alpha-1}}$. Note that if all $w_{i_1 i_2}$ are small, the energy saving will be even more significant.

Actually, this result could be extended to jobs with VMs assigned in more than one rack. However, we assume that this is sufficient because in [?] the authors pointed out that most jobs can be fitted into a single rack in a large-scale data center and in general few jobs will share a link at the same time. Moreover, the most important reason why we use this principle in our model is that it is time-varying. In our model, we will assign jobs with complementary traffic patterns into the same pod. This way, the interference between different jobs can be highly reduced, making our assumption for this principle reasonable.

4.1.3 Arranging VMs among Pods

The last principle we propose is how to assign VMs among pods. Basically, we want to answer the following question: is it better to assign all the VMs from the same job to different pods or to put them together in one single pod?

Theorem 6. (*Principle 3*) *As long as there are enough resources in one pod, the optimal assignment will never split VMs from the same job to different pods.*

Proof. Suppose we have one job with all its VMs assigned to a single pod A . Now we consider moving some VMs from A to a new pod B . Consider the simple case where we move the VMs assigned from one whole rack in A to an empty rack in B . Due to the connectivity property of fat-tree that for each aggregation switch, the outer fan-out (to other pods) is not larger than the inner fan-out (to ToR switches within the pod), the number of node-disjoint paths between any two ToR switches in A will not be smaller than the ones between two ToR switches in A and B respectively. As a result, moving the VMs from a whole rack to a different pod will never reduce the traffic on any ToR or aggregation switch, it will bring extra traffic in core switches, not reducing the power consumption. Then, it can be also inferred that moving some VMs to another pod is not beneficial due to the same reason. $\square$

4.2 Traffic-Aware Energy-Efficient VM Assignment

We devise our VM assignment algorithm using the three proposed principles. This algorithm will assign VMs with favorable traffic patterns for saving energy on the network by perfectly observing these principles. The algorithm takes a set of jobs (sets of VMs) and its traffic communication patterns and a set of servers as input, and returns a job (VMs) assignment after processing the three steps listed in Algorithm 1.

Firstly, we carry out a transformation to the VMs. As in our model each server can host multiple VMs, this will bring high complexity to the subsequent steps. Before the VM assignment, we transform the VMs into super-VMs which will be assigned alone to single servers based on the following proposition.

Proposition 7. *Compacting the VMs with high communication traffic will reduce the network power consumption.*

Algorithm 1 Traffic-Aware Energy-Efficient VM Assignment

Input: data center topology $G = (V, E)$, set of servers S and set of jobs J

Output: assignment for all the VMs for all jobs

- 1: **for** $j \in J$ **do**
 - 2: Transform VMs to super-VMs
 - 3: **end for**
 - 4: Cluster jobs in J into groups S_i for $i \in [1, N_p]$ and S_{N_p+1}
 - 5: **for** $1 \leq i \leq N_p$ **do**
 - 6: Partition the super-VMs for each job $j \in S_j$ into K parts using the min- k -cut algorithm
 - 7: Assign the super-VMs of each job into servers according to the partition
 - 8: **end for**
 - 9: Assign the VMs of jobs in S_{N_p+1} into vacancy servers in the first N_p pods flexibly.
-

Proof. It can be easily observed from the fact that the traffic between any VMs assigned to the same server does not go to the physical NICs on the host server, as well as the network. Then, it is quite natural to assign VMs for the same job to the same servers in order to reduce the network traffic. In this sense, compacting VMs with high communication traffic will reduce the traffic on the network, resulting in more energy savings. $\square$

To complete this transformation, we define a referential traffic matrix $\mathbf{T}_j^{\text{ref}}$ for each job $j \in J$, where

$$\mathbf{T}_j^{\text{ref}}(x, y) = \sum_{t=t_1}^{t_r} \mathbf{T}_j(t)(x, y) \quad \forall x, y \in [1, n_j].$$

We shrink VMs to super-VMs as follows. For each job $j \in J$, we run the following process iteratively: in each iteration, we choose the biggest value in matrix $\mathbf{T}_j^{\text{ref}}$. Suppose this value exists in the x_1 -th row and y_1 -th column. Then, we combine the x_1 -th VM with the y_1 -th one by removing the traffic between them and adding up their traffic with other VMs. After that, we choose the biggest value in the x_1 -th row and y_1 -th row, and combine the corresponding VMs. We denote the VM after this shrink as a super-VM. Repeat this procedure until the resources of one server are maximumly utilized if we assign this super-VM to a server. Then, we remove all the VMs that have been chosen and shrunk from the matrix, and find the next biggest value to start a new iteration. With this transformation, all the jobs will be represented by super-VMs each one assigned to one single server.

Secondly, we partition the jobs into different pods. Before that, we assume that every job can be accommodated in a single pod. Nevertheless, if there were huge jobs requiring more than one pod, they can be assigned in a greedy way and then consider assigning the residual normal jobs. From Principles 1 and 3 we know that the number of pods used for accommodating all the jobs has to be minimized. In other words, it is not wise to separate the super-VMs for

the same job into different pods if this job can be assigned into a single pod. Based on this, we estimate the number of pods to be used by summing up the resource requested by all the jobs. We denote the estimated number of pods as N_p . Then, we partition the set of jobs into those N_p pods by using a revised k -means clustering algorithm which takes the traffic patterns of the jobs into account. With the intuition that it is better to consolidate jobs with strongly different traffic patterns into the same pod to improve the utilization of network equipments, the algorithm will compare the traffic patterns of jobs and cluster them into different groups, where in each group, the jobs in it will enjoy the maximized difference of communication patterns.

To this end, we first calculate a traffic pattern vector $\mathbf{v}_j$ with size r for each job $j \in J$. Each dimension of $\mathbf{v}_j$ indicates the average traffic between any two VMs of job j in each unit of time and is calculated as

$$T_j^{avg}(t) = \frac{\sum_{xy \in [1, n_j]} \mathbf{T}_j(t)(x, y)}{n_j^2/2}, \quad (5)$$

if $t \in [t_{js}, t_{jt}]$; otherwise we set T_j^{avg} to ϵ where ϵ is infinitesimal. The traffic pattern vector now can be expressed as

$$\vec{\mathbf{v}}_j = (T_j^{avg}(t_1), T_j^{avg}(t_2), \dots, T_j^{avg}(t_r)).$$

We then give the following definition.

Definition 8. Given two jobs $j_1, j_2 \in J$ with traffic pattern vectors $\vec{\mathbf{v}}_{j_1}$ and $\vec{\mathbf{v}}_{j_2}$ respectively, the distance between the two jobs is defined as

$$dis(j_1, j_2) = dis(\vec{\mathbf{v}}_{j_1}, \vec{\mathbf{v}}_{j_2}) = \frac{1}{\|\vec{\mathbf{v}}_{j_1} - \vec{\mathbf{v}}_{j_2}\|_2}.$$

This definition of distance supposes that any two jobs with similar traffic patterns will receive a big distance between them. Having these distance vectors, the clustering algorithm works as follows: 1) Choose N_p jobs and put them into sets S_i for $i \in [1, N_p]$ with one job per set. Use the traffic pattern vectors of these jobs as center vectors $\vec{\mathbf{c}}_i$ of these sets. We adopt this initializing step from the refined k -means++ algorithm [?]. In the traditional k -means algorithm, the initial cluster centers are chosen randomly, which will lead to arbitrarily bad results. Compared to the traditional one, the k -means++ algorithm can guarantee an approximation ratio $O(\log N_p)$ in expectation. 2) For each of the residual jobs j , find the nearest cluster i with respect to the distance $dis(\vec{\mathbf{v}}_j, \vec{\mathbf{c}}_i)$. If this job can be accommodated into this cluster without any resource violation, put this job into set S_i . Otherwise choose the next one with a larger distance and repeat until there is one cluster found to accommodate it. 3) Update the center vector of cluster i by averaging all the vectors of jobs in set S_i .

$$\vec{\mathbf{c}}_i = \frac{\sum_{j \in S_i} \vec{\mathbf{v}}_j}{|S_i|} \quad \forall i \in [1, N_p]$$

Repeat 2) and 3) until all the jobs have been assigned. If there are some jobs that cannot find any cluster to accommodate, put them into an extra set S_{N_p+1} .

Thirdly, we choose N_p free pods and assign the jobs in each cluster to one pod. Inspired by Principle 2, we distribute the super-VMs of each job into multiple-racks. The simplest way is to randomly partition these super-VMs into K racks, where K is the total number of racks in one pod. However, as we have stated before, it is better to allocate the VMs with the highest traffic flows into the same rack. Then, the problem becomes to partition the set of super-VMs into K parts such that the traffic between each part of the partition is minimized. This is equivalent to the well-known minimum k -cut problem that requires finding a set of edges whose removal would partition a graph to k connected components. The partition algorithm used here is adopted from the minimum k -cut algorithm in [?]. For each job j , we build a graph $G_j = (V_j, E_j)$, where V_j represents the set of super-VMs and E_j represents the traffic between each pair of super-VMs. Then, we compute the Gomory-Hu tree for G' and obtain $n_j - 1$ cuts $\{g_i\}$ which contains the minimum weight cuts for all super-VM pairs. We remove the smallest $K - 1$ cuts from $\{g_i\}$ and get K connected components of G' . For the super-VMs in the same components, we regard them as a super-VM cluster and will assign them into the same rack.

After obtaining all the partitions of the jobs in every pod, we now try to assign these partitions into racks. For each job, we sort the super-VM clusters in decreasing order according to the cluster size. After that, we assign each cluster of the job to racks in a greedy manner. When the assignment of a job has been done, we sort all the racks in increasing order according to the number of used servers and assign the next job by repeating the above process, until all the jobs have been assigned. At last, we assign the jobs in set S_{N_p+1} to the N_p pods flexibly. Note that this can be accomplished because N_p is computed by the total resources required, and with N_p pods, all the jobs should be accommodated.

5 Energy-Efficient Routing

In this section, we focus on traffic engineering in DCNs to achieve energy conservation. We first explore the relation between energy consumption and routing and then, based on this relation, we design a two-phase energy-efficient routing algorithm.

5.1 Exploring Energy Saving Properties

As we have discussed in the previous section, in reality we have $R^* > C$. In order to achieve energy saving, we need to answer the following questions: how many switches will be sufficient and how to distribute the traffic flows? In this section, we will explore the relation between energy saving and routing, and answer these questions.

The second question is easy to answer once we have solved the first one. With the optimal number of switches determined, the best way to achieve energy

saving is to balance the traffic among all the used switches, due to the convex fashion power being consumed. In DCNs, this can be done by many multi-path routing protocols such as Equal Cost Multi-Path (ECMP) and Valiant Load Balancing (VLB). This is because data centers usually have networks with reacher connectivities, and these multi-path routing protocols use hash-based or randomized techniques to spread traffic across multiple equal cost paths. Some more sophisticated techniques such as Hedera [?] and MPTCP ([?, ?]) can also be applied to ensure uniform traffic spread despite flow length variations.

To answer the first question, we first concentrate on the aggregation switches (we have shown that nothing can be done with ToR switches once we have the VMs assigned). In general, we show the following lemma.

Lemma 9. *The optimal energy-efficient routing algorithm will use as few aggregation switches as possible.*

Proof. We focus our attention on the aggregation switches in one pod. Recall in fat-tree topology shown in Figure 2, the connectivity between the ToR switches and the aggregation switches is supported by all-to-all mapping links. Thus, we can choose any aggregation switch to carry any flow coming out or going into a ToR switch. Denote the minimum number of aggregation switches to be used as N_a . We will show that for any $n \geq N_a$, the minimum total power consumption of the aggregation switches obtained using n aggregation switches will be always smaller than the one obtained using $n + 1$ aggregation switches.

Assume in the optimal solution with n aggregation switches, the total load going through the i -th aggregation switch is $p_i \in (0, C]$ ($1 \leq i \leq n$), while using $n + 1$ aggregation switches, this value is $q_i \in (0, C]$ ($1 \leq i \leq n + 1$). Since all the switches are identical, without loss of generality, we assume that q_{n+1} is the most loaded one among all q_i , and p_i and the residual q_i are sorted in descending order. Denote $\delta_i = p_i - q_i$ for $1 \leq i \leq n$ then, we have $q_{n+1} = \sum_{i=1}^n \delta_i$. Since both solutions are optimal, it can be observed that $\delta_i \geq 0$ for $1 \leq i \leq n$. Using n switches, the total power consumption is presented as

$$P(n) = n\sigma + \mu \sum_{i=1}^n p_i^\alpha,$$

while using $n + 1$ switches it is

$$P(n+1) = (n+1)\sigma + \mu \sum_{i=1}^n (p_i - \delta_i)^\alpha + \left(\sum_{i=1}^n \delta_i \right)^\alpha.$$

To complete the proof, it is sufficient to show that for any $n \geq N$, we have $P(n+1) \geq P(n)$. Denote the difference between the two optimal solutions as ΔP . Then,

$$\Delta P = P(n+1) - P(n) = b + \mu \sum_{i=1}^n ((p_i - \delta_i)^\alpha - p_i^\alpha) + \mu \left(\sum_{i=1}^n \delta_i \right)^\alpha.$$

Note that ΔP is a function of variables $\mathbf{p}$ and $\boldsymbol{\delta}$, where $\vec{\mathbf{p}} = (p_1, p_2, \dots, p_n)$ and $\vec{\boldsymbol{\delta}} = (\delta_1, \delta_2, \dots, \delta_n)$. Since $\vec{\mathbf{p}}$ and $\vec{\boldsymbol{\delta}}$ are independent and $\delta_i \geq 0$, ΔP is minimized

when we set $\vec{x} = (C, C, \dots, C)$. That is,

$$\begin{aligned}
\Delta P &\geq \sigma + \mu \sum_{i=1}^n ((C - \delta_i)^\alpha - C^\alpha) + \mu \left(\sum_{i=1}^n \delta_i \right)^\alpha \geq \sigma + \mu \left(\sum_{i=1}^n \left(\frac{nC}{n+1} \right)^\alpha - \sum_{i=1}^n C^\alpha \right) \\
&\geq \mu C^\alpha + \mu \left((n+1) \left(\frac{nC}{n+1} \right)^\alpha - nC^\alpha \right) = \mu C^\alpha \left((\alpha - 1) + n \left(\left(\frac{n}{n+1} \right)^\alpha - 1 \right) \right) \\
&\geq \mu C^\alpha \left(\alpha - 1 + n \left(\frac{n+1}{n+\alpha} - 1 \right) \right) = \mu C^\alpha \frac{\alpha(\alpha - 1)}{n + \alpha} > 0,
\end{aligned}$$

when $\alpha > 1$. The second inequality comes from the fact that ΔP is minimized when we set $\vec{\delta} = \left(\frac{C}{n+1}, \frac{C}{n+1}, \dots, \frac{C}{n+1} \right)$. The third inequality is due to the restriction that $\sigma \geq \mu C^\alpha (\alpha - 1)$. The fourth inequality is obtained by applying the necessary condition on n that the first derivative equals zero. Having $\Delta P \geq 0$ means that using fewer aggregate switches results in better energy efficiency. $\square$

The same technique can also be applied to the core switches if we ensure each flow can be routed by the candidate core switches when we choose aggregation switches in each pod. This is easy to achieve if we choose aggregation switches from the same positions in different pods and for sure there will be core switches connecting each pair of them. Taking all together, we have

Theorem 10. *In the optimal energy-saving solution, the number of active switches is minimized.*

5.2 Two-Phase Energy-Efficient Routing

Based on the answers to the two questions we asked at the beginning of this section, we devise an energy-efficient routing algorithm, as listed in Algorithm 2. For each unit of time, we repeat the following two phases. In the first phase, the algorithm devotes to find a subset of switches in a bottom up manner. The estimation of active switches is accomplished by a simple calculation where we divide the total traffic by the capacity of the switch. However, as it can happen that the multipath routing algorithm may not evenly distribute the traffic flows perfectly, we use the first fit decreasing algorithm, a good approximation for bin-packing problem where we treat the flows as objects and the maximum transmission rate of the switch as the bin size, to ensure that all the traffic flows can be routed using the selected switches.

In the second phase, we borrow the most recently proposed multipath routing protocol, MPTCP, to route all the flows. Compared to the single path routing for each flow in randomized load balancing techniques, MPTCP can establish multiple subflows across different paths between the same pair of endpoints for a single TCP connection. It can be observed that randomized load balancing may not achieve the evenly distribution of traffic because a random selection causes hot-spots to develop, where an unlucky combination of random path selection causes a few links to be underloaded and links elsewhere to have litter or no

Algorithm 2 Two-Phase Energy-Efficient Routing

Input: data center topology $G = (V, E)$, set of servers S and VM assignment**Output:** routes of flows

```
1: for  $t \in [t_1, t_r]$  do
2:   Obtain the traffic flows on the network at time  $t$  according to the VM
   assignment
3:   for  $i \in [1, N_p]$  do
4:     Estimate the number  $N_{ai}$  of aggregation switches that will be used in
     the  $i$ -th pod
5:     Choose the first  $N_{ai}$  aggregation switches in this pod
6:   end for
7:   Estimate the number  $N_c$  of core switches that will be used and choose
   them
8:   Use multipath routing to distribute all the flows evenly on the network
   formed by the selected switches
9:   Turn the unused switches into sleep mode
10: end for
```

load. By linking the congestion control dynamics on multiple subflows, MPTCP can explicitly move traffic away from the more congested paths and place it on the less congested paths. A sophisticated implementation of MPTCP in data centers can be found in [?]. The unused switches will be turned into sleep or some other power-saving mode where few power is needed to maintain the state. Due to the way we assign VMs, the network state will maintain the same most of the time. Very few state changes will be needed on only a small amount of switches. According to the routes of flows, the routing tables are generated and sent to corresponding switches in runtime by a centralized controller and the OpenFlow realization in switches.

6 Experimental Results

In this section, we provide the detailed experimental findings. We associate a cost functions to the switches in real data centers, implement our VM assignment and network routing algorithms presented in the previous sections, and compare the energy consumption against the solutions obtained by commonly used greedy VM assignment and multi-path routing.

6.1 Experimental Settings

We conduct a simulator with our algorithms implemented in Python and run all the simulations on a desktop with an Intel Core 2 T8700 CPU and 4 GB memory. We choose the following parameters for our model in the experiments. We use fat-trees as the topologies of data centers. We assume that the VMs used in all the jobs are identical and each server can handle two VMs. For all the switches in a data center, we use a uniform power function $f(x) = \sigma + \mu x^\alpha$,

Figure 4: Energy consumption using single path routing and ECMP routing algorithms in a data center network with 16 servers connected by a fat-tree

and we set $\sigma = 200$ Watts, $\mu = 1 \times 10^{-4}$ and $\alpha = 2$ (x will use Gbps as the unit). Assuming the processing speed of a switch is limited by 1 Tbps, the maximum power consumption of one single switch will be 300 Watts. These parameters are chosen based on the real statistics of commodity switches as we have discussed at the beginning of Section 4 and also our assumption $R^* > C$ is maintained. We select a time period with length 100 minutes (with the unit minute) as our interest and assume during the 100 minutes, we have a set of jobs needing to be processed in a data center. The jobs are generated randomly where the number of VMs each job requests follows a normal distribution $\mathcal{N}(K, 0.5K)$ (K is the size of a rack). We associate each job with a communication-intensive time interval which is uniformly distributed in the 100 minutes. In each minute of this communication-intensive interval, a traffic matrix is provided to indicate the traffic pattern between each pair of the VMs for that job. The traffic loads in this matrix is generated following by a normal distribution $\mathcal{N}(50, 1)$ Mbps.

We select benchmarks to show the efficiency of our algorithms. To evaluate the efficiency of our VM assignment algorithm, we compare our results to the greedy assignment which assigns VMs to servers one by one such that the requested resource by VMs can be satisfied and is commonly used in production data centers. To evaluate the efficiency of our routing optimization, the normal ECMP is a perfect evaluating ruler for us because our routing algorithm is also established on multi-path routing. However, in order to get the exact energy consumption results, the normal ECMP algorithm needs to perform the routing procedure entirely and thus runs quite slow with large-scale topologies. In order to obtain the results in reasonable time, we choose single-path (SP) routing to take over from the normal ECMP. Being a very sophisticated routing protocol, single-path routing has been implemented in most traditional networks and some production data center networks. We implement single-path routing with the Dijkstra shortest path algorithm. In order to make our comparison fair, we first study the relation between the energy consumption of ECMP and SP in small-scale data center networks with a 4-ary fat-tree topology. We tested with different amounts of load of the data center and recorded the energy consump-

Figure 5: Energy saving ratios using different VM assignment methods and routing algorithms in two data center networks in different scales with (a) 1024 and (b) 3456 servers connected respectively. The ratios are obtained as the energy consumption normalized by the ones consumed using Greedy-SP

tion under each case with both ECMP and SP. The experimental results have been shown in Figure 4. It can be observed that ECMP consumes more energy than SP all the time no matter how much load the data center carries. This is mainly because with the same amount of traffic, ECMP uses more switches to route them, and according to Theorem 10, this will in turn bring more energy consumption. As a result, using SP to evaluate our algorithm is appropriate instead of ECMP.

6.2 Efficiency of Energy Savings

We test our VM assignment and energy-efficient routing (EER) algorithm using two fat-tree topologies in different scales, with 1024 and 3456 servers connected respectively. We range the loads of data centers from 5% to 95% and compared the energy consumptions under different data center utilizations. For each scheduling instance, we compare 5 values of interest, the greedy assignment and SP routing solution, the optimized greedy (OptGreedy) assignment and SP routing solution, the greedy assignment and EER solution, the energy-efficient assignment (EEA) and EER solution and the optimized EEA (OptEEA) and EER solution. The optimized greedy assignment applies the VM to super-

VM transformation in our algorithm before the normal greedy assignment and OptEEA is our whole algorithm for VM assignment. The five curves in Figure 5 (a) and (b) correspond to the ratio of these 5 values all normalized by the greedy assignment and SP routing solution. We observe the following.

- a) The energy-efficient routing algorithm can provide substantial energy savings even the greedy assignment algorithm is being used. Up to 30% reduction on network energy consumption can be achieved by applying this routing optimization in data center networks.
- b) The well-designed VM to super-VM transformation is very helpful in reducing the network energy consumption. As we have discussed, the traffic on the network will be reduced by applying this transformation.
- c) The distributed manner of VM assignment in each pod can bring us at least 5% energy-savings. However, while combined with the VM to super-VM transformation and energy-efficient routing, the energy saving ratio will be as large as 50%. Compared to the energy saving brought by the energy-efficient routing, the whole VM assignment optimization we proposed can bring us about 20% more savings.

This convinces us that the room for saving energy in current data center networks remains quite big, and a huge amount of energy can be saved by not only traffic engineering, but also an integrated optimization of applications, VM assignment and routing, confirming the advantage of our framework.

6.3 Running Time

To ensure that our VM assignment algorithm can be carried out in big data centers, we have recorded also the running times of the used algorithms in our experiments. The numerical results are presented in Figure 6. We find that with the smaller-scale topology, our algorithm can be finished in one second, while with the larger-scale topology, the running time is within 10 seconds. Compared to the greedy algorithm, the running time of our algorithm is only 50 percent more than the greedy one. We have also tested our algorithm with large-scale topologies (with tens thousands of servers), most of the time, the running time is bounded by 2 minutes which is quite acceptable in production data centers.

7 Discussion

The proposed algorithms have been shown to have good quality on improving the energy efficiency of data center networks. Now we devote to discuss how to make them practical with respect to those assumptions we have made before.

As to simplify the modeling and analyzing, we assumed to use the single peak model to represent the communication patterns of jobs. However, the authors in [?] have pointed out that the traffic patterns of these jobs can mainly

Figure 6: Running times used by our energy-efficient VM assignment algorithm and the greedy algorithm in two data center networks in different scales with (a) 1024 and (b) 3456 servers connected respectively

be classified into three categories: single peak, repeated fixed-width peaks and varying height and width peaks. Recall that in our model, the only place we refer to this traffic pattern information is the generation of traffic pattern vectors. It can be noticed that even with the most complicated pattern, this generation process can be simply adapted with only a slight change on the expressions.

The model we propose in this paper is a suitable adoption for offline cases. However, in production data centers, we probably have cases with dynamic job arriving or leaving. We argue that the proposed algorithms can also be applied to online cases because the information interaction of jobs in our proposed algorithms is very few. One possible adaption can be that for each job arrived, we first apply the VM to super-VM transformation, and then compute the distances between it and the other jobs running in the data center. According to the distances, we assign this job into a pod and then the rest of our energy-efficient VM assignment algorithm, as well as the energy-efficient routing, can be directly applied. We leave a deliberated adaption to online cases as future work.

8 Related Work

We summarize some related work on network-related optimization in data centers, including VM assignment, traffic engineering, as well as energy-efficient data center networking.

8.1 VM Assignment and Traffic Engineering

Traffic engineering in DCNs has been extensively studied. Due to the centralized environment of data centers, centralized controllers are broadly used to schedule or route traffic flows. AL-Fares et al. proposed Hedera [?], which is a scalable, dynamic flow scheduling system that adaptively schedules a multi-stage switching fabric to efficiently utilize aggregate network resources. Benson et al.

[?] proposed MicroTE, a system that adapts to traffic variations by leveraging the short term and partial predictability of the traffic matrix, to provide fine-grained traffic engineering for data centers. Abu-Libdeh et al. [?] realized that providing application-aware routing services is advantageous. They proposed a symbiotic routing to achieve specific application-level characteristics.

Recently, data center network virtualization architectures such as Second-Net [?] and Oktopus [?] have been proposed. Both of them consider the virtual cluster allocation problem, i.e., how to allocate VMs to servers while guaranteeing network bandwidth. In a recent work, Xie et al. [?] proposed TIVC, a fine-grained virtual network abstraction that models the time-varying nature of networking requirement of cloud applications, to better utilize networking resources. Meng et al. [?] proposed to use traffic-aware VM placement to improve the network scalability. Then, they explored how to achieve better resource provisioning using VM multiplexing by exploring the traffic patterns of VMs [?]. In a follow-up work [?], they studied how to consolidate VMs with dynamic bandwidth demand by formulating a Stochastic Bin Packing problem and proposed an online packing algorithm. Jiang et al. [?] explored how to combine VM placement and routing for data center traffic engineering, and provided an efficient on-line algorithm for it. However, they didn't consider the temporal information of the communication patterns of the applications and the topologies features.

8.2 Energy Efficient Data Center Networking

Many approaches have been proposed to improve the energy efficiency of DCNs. These techniques can be usually classified into two categories: The first one is to design new topologies which use less network devices while guaranteeing similar performance and connectivity, such as the flattened butterfly proposed by Abts et al. [?] or PCube [?], a server-centric network topology for data centers, which can vary bandwidth availability based on traffic demands; The second one is to find optimization methods for current DCNs. The most representative work in this category is *ElasticTree* [?], a network-wide power manager which can dynamically adjust the set of active network elements, to satisfy variable data center traffic loads. Shang et al. [?] considered saving energy from a routing perspective, routing flows with as less network devices as possible. Mahadevan et al. [?] discussed how to reduce the network operational power in large-scale systems and data centers. Recently, Wang et al. [?] proposed CARPO, a correlation-aware power optimization algorithm that dynamically consolidates traffic flows onto a small set of links and switches and shut down unused network devices. Zhang et al. [?] proposed a hierarchical model to optimize the power in DCNs and proposed some simple heuristics for it. To the best of our knowledge, this is the first paper to address the power efficiency of DCNs from a comprehensive point of view, leveraging an integration of many useful properties we can take advantage of in data centers.

9 Conclusion

In this paper, we study the problem of achieving energy efficiency in DCNs. Unlike traditional traffic engineering based solutions, we provide a new general framework where some unique features of data centers have been used. Based on this framework, we define an energy saving problem with a time-aware model and prove its NP-hardness. We solve the problem in two steps. First, we carry out a purposeful VM assignment algorithm that provides favorable traffic patterns for energy-efficient routing, based on three VM assignment principles we propose. Then, we analyze the relation between the power consumption and routing and then propose a two-phase energy-efficient routing algorithm. This algorithm aims to minimize the number of switches that will be used and to balance traffic flows among them. The experimental results show that the proposed framework provides substantial benefit in terms of energy savings. By combining VM assignment and routing, up to a 50% of the energy can be saved. Moreover, the proposed algorithms can be run in reasonable time and can be applied in large-scale data centers.
